

# EFFECTS OF APPLYING LINEAR AND NONLINEAR FILTERS ON TESTS FOR UNIT ROOTS WITH ADDITIVE OUTLIERS

MIGUEL A. ARRANZ, ALVARO ESCRIBANO, AND FRANCESC MARMOL

ABSTRACT. Conventional univariate Dickey-Fuller tests tend to produce spurious stationarity when there exist additive outlying observations in the time series. Correct critical values are usually obtained by adding dummy variables to the Dickey-Fuller regression. This is a nice theoretical result but not attractive from the empirical point of view since almost any result can be obtained just by a convenient selection of dummy variables. In this paper we suggest a robust procedure based on running Dickey-Fuller tests on the trend component instead of the original series. We provide both finite-sample and large-sample justifications. Practical implementation is illustrated through an empirical example based on the US/Finland real exchange rate series.

*Key words:* Additive outliers, Dickey-Fuller test, linear and nonlinear filtering, bootstrap.

*J.E.L. Classification:* C15, C52, E32.

This draft: September 2002

## 1. INTRODUCTION

Univariate and multivariate unit root testing procedures are sensitive to the occurrence of anomalous events such as structural breaks and outliers. From the univariate point of view, the effects of having breaks when applying unit root tests are well documented. Perron (1989) shows that standard unit root tests break down (finding too many unit roots) if there is a structural break in the data generating process, such as a level shift. The intuitive idea is that the unit root hypothesis is closely associated with shocks having a permanent effect. A structural break essentially corresponds to a shock with a lasting effect on the series (see Perron and Vogelsang, 1992). Thus, if this shock is not explicitly taken into account, standard unit root tests will identify the structural break as a unit root. On the contrary, if the break occurs early in the series, unit root tests can lead to over-rejection of the unit root hypothesis (see Leybourne et al., 1998).

A possible solution to this problem requires the use of dummy variables and segmented trends. For instance, Perron (1989) included a set of deterministic regressors to allow for an alternative hypothesis having a trend break at a known date. The main problem with this procedure is that,

---

This paper is a substantially revised version of Arranz and Escribano (1998), presented at the EC2 Conference in Stockholm and the Econometric Society European Meeting in Santiago de Compostela. Francesc Marmol thanks DGICYT grant PB98-0026. This research was also partially financed with grants PB98-0030 and TMR ERB-4061PL87-094.

even if we know when the structural break occurs, the critical values obtained depend on the size as well as on the timing of the break. Additionally, the asymptotic distributions of unit root tests also depend on whether the location of the breaks is known from the outset or not (see, e.g. Christiano, 1992).

Another type of anomalous events are the additive transitory outliers. These are events with a (possible) large but temporary effect on the series. Provided these additive outliers (AO's) are sufficiently large or sufficiently frequent, such an effect can dominate the remaining information contained in the series and biases unit root inference towards rejection of the unit root hypothesis, as reported by Martin and Yohai (1986), Franses and Haldrup (1994), Lucas (1995*a,b*), Shin et al. (1996), and Vogelsang (1999), among others.

In principle, it is possible to include dummy variables for these transitory shocks as is usually done in the case of structural breaks and calculate the corresponding new critical values. See Franses and Haldrup (1994), Shin et al. (1996), and Vogelsang (1999). A crucial step in this approach, however, turns out to be the detection of the AO's. Tsay (1986), Chang et al. (1988), Chen and Liu (1993), Gómez and Maravall (1996) and Kaiser (1998) provide some of the most common procedures to identify isolate outliers. For practical purposes, however, it requires a considerable skill to identify the outliers and evaluate the many different test statistics. Alternatively, one could avoid the use of dummy variables by considering robust estimation techniques following the approach by Lucas (1995*a,b*). Hence, the main idea of outlier detection is to throw them out, whereas the basic idea of robust estimation is to leave them in. See Maddala and Yin (1996) and Yin and Maddala (1997) for further insights.

Within the robust approach, in this article we explore a different route for testing for a unit root when AO's are a possibility in the data. Assume the series of interest,  $z_t$ , is split in two unobserved components,  $z_t = z_t^g + z_t^c$ , where  $z_t^g$  denotes the permanent or trend component and  $z_t^c$  stands for the transitory or cyclical component. Our proposal is to apply the unit root tests to  $z_t^g$  instead of the observed series  $z_t$ , the idea being that, since the AO's are transitory, they could be incorporated, to a large extent, into the cyclical component  $z_t^c$  and not into the trend. To estimate the growth component  $z_t^g$ , we suggest the use of low-pass filters.

The paper is organized as follows. In Section 2 we introduce the model of interest and some analytical results concerning the effects of frequency and size of AO's on the well-known Dickey-Fuller test statistic. Section 3 presents some basic results on filtering and signal extraction. In Section 4 we discuss the effects of filtering on the Dickey-Fuller tests. Section 5 presents some Monte Carlo evidence to illustrate the finite sample implications of our analytical findings. Section

6 provides an empirical example and Section 7 concludes. Proof of Theorem 1 is collected in an Appendix.

## 2. UNIT ROOTS AND ADDITIVE OUTLIERS

Let  $y_t$  be generated by a random walk with  $y_0 = 0$ ,

$$y_t = y_{t-1} + \varepsilon_t, \quad t = 1, 2, \dots, T, \quad (2.1)$$

where  $\varepsilon_t$  are independent and identically distributed (i.i.d.)  $N(0, \sigma_\varepsilon^2)$  variates, and suppose systematic AO's of size  $\pm\theta$  may occur with probability  $\pi$ , so that the time series we observe is

$$x_t = y_t + \theta\delta_t, \quad (2.2)$$

where  $\delta_t$  are i.i.d. Bernoulli random variables such that  $P(\delta_t = 1) = \frac{1}{2}\pi$ ,  $P(\delta_t = -1) = \frac{1}{2}\pi$  and  $P(\delta_t = 0) = 1 - \pi$ ,  $\delta_0 = 0$ .

Consider the unit root regression

$$\Delta y_t = \rho y_{t-1} + \varepsilon_t. \quad (2.3)$$

As is well-known, the Dickey-Fuller unit root test takes as null hypothesis  $H_0 : \rho = 0$ , unit root, against  $H_1 : \rho < 0$ , stable root. The test is implemented by means of the least squares estimate of  $\rho$ ,

$$\hat{\rho} = \left( \sum_{t=1}^T y_{t-1} \Delta y_t \right) / \left( \sum_{t=1}^T y_{t-1}^2 \right), \quad (2.4)$$

and the corresponding  $t$  statistic for a zero coefficient,

$$t_{\hat{\rho}} = \hat{\rho} / \widehat{\sigma}_y \left( \sum_{t=1}^T y_{t-1}^2 \right)^{-1/2}, \quad (2.5)$$

where  $\widehat{\sigma}_y^2 = T^{-1} \sum_{t=1}^T (\Delta y_t - \hat{\rho} y_{t-1})^2$  is the residual variance,  $\Delta = (1 - L)$  and  $L$  is the lag operator defined so that  $L^n y_t = y_{t-n}$  for positive and negative values of  $n$ .

Note from equation (2.2) that, in the presence of AO's, regression (2.3) becomes

$$\Delta x_t = \rho x_{t-1} + u_t, \quad (2.6)$$

where  $u_t = \varepsilon_t + \theta\Delta\delta_t$  with corresponding least squares statistics

$$\hat{\rho}_{AO} = \left( \sum_{t=1}^T x_{t-1} \Delta x_t \right) / \left( \sum_{t=1}^T x_{t-1}^2 \right), \quad (2.7)$$

and

$$t_{\widehat{\rho}_{AO}} = \widehat{\rho}_{AO} \left/ \widehat{\sigma}_x \left( \sum_{t=1}^T x_{t-1}^2 \right)^{-1/2} \right., \quad (2.8)$$

where  $\widehat{\sigma}_x^2 = T^{-1} \sum_{t=1}^T (\Delta x_t - \widehat{\rho}_{AO} x_{t-1})^2$ . Therefore, under  $H_0$ , the observed series turns out to be an  $I(1)$  process with  $MA(1)$  innovations, since  $E(u_t u_{t-1}) = -\pi\theta^2$ ,  $E(u_t u_{t-j}) = 0$  for  $j > 1$ . Consequently,  $u_t$  satisfies Phillips (1987) general mixing conditions, and a functional central limit theorem applies to the partial sums of  $u_t$ , so that the asymptotic distribution of (2.7) and (2.8) can be derived. In particular, it can be proved that, as  $T \rightarrow \infty$ ,

$$\begin{aligned} T\widehat{\rho}_{AO} &\Rightarrow \left( \int_0^1 W(r) dW(r) \right) \left/ \left( \int_0^1 W^2(r) dr \right) \right. \\ &\quad \left. - (\theta/\sigma_\varepsilon)^2 \pi \left( \int_0^1 W^2(r) dr \right)^{-1} \right. \end{aligned} \quad (2.9)$$

and

$$\begin{aligned} t_{\widehat{\rho}_{AO}} &\Rightarrow \left( 1 + 2(\theta/\sigma_\varepsilon)^2 \pi \right)^{-1/2} \\ &\quad \times \left( \int_0^1 W(r) dW(r) \right) \left/ \left( \int_0^1 W^2(r) dr \right)^{1/2} \right. \\ &\quad \left. - (\theta/\sigma_\varepsilon)^2 \pi \left( \int_0^1 W^2(r) dr \right)^{-1/2} \right., \end{aligned} \quad (2.10)$$

where  $\Rightarrow$  denotes weak convergence and where  $W(r)$  is a standard Brownian motion defined on the unit interval  $r \in [0, 1]$ .

Equations (2.9) and (2.10) were first derived by Franses and Haldrup (1994). From these equations we learn that if  $\pi > 0$ ,  $\rho$  is still estimated superconsistently, but the asymptotic distributions of the Dickey-Fuller statistics shift to the left, leading to tests with exact size greater than asymptotic nominal size and, consequently, to over-reject the unit root hypothesis in favor of the stationary alternative. Note that a positive AO and a negative AO with the same magnitude have the same effect on the limiting distributions. Note also that distributions are the same for any combination of  $\theta$ ,  $\pi$  and  $\sigma_\varepsilon^2$  giving rise to the same value of  $(\theta/\sigma_\varepsilon)^2 \pi$ . In other words, large shocks with small chance of occurrence have the same effect as that of small shocks with high probability of occurrence. The Dickey-Fuller tests simply cannot distinguish infrequent large shocks from frequent small shocks. On the other hand, Franses and Haldrup's findings are readily extended to models allowing for the presence of deterministic components as well. See Yin and Maddala (1997).

## 3. FILTERS AND SIGNAL EXTRACTION

Filter techniques have been used for a long time in estimating the states of stochastic dynamic systems or in extracting information from noisy observations. These techniques are also widely adopted in economics, specially with macroeconomics series. The usual aim of filtering in this latter case is to isolate the business cycle component of the series from slowly evolving secular trends and rapidly varying seasonal or irregular component.

For simplicity, assume that we are interested in splitting an observed time series,  $z_t$ , in two unobserved components,

$$z_t = z_t^g + z_t^c, \quad (3.1)$$

where  $z_t^g$  is the growth or trend component and  $z_t^c$  stands for the cyclical component. Note that (3.1) can be rewritten as

$$z_t = z_t^g + (z_t - z_t^g), \quad (3.2)$$

or

$$z_t = (z_t - z_t^c) + z_t^c. \quad (3.3)$$

Equation (3.2) requires a definition of the trend component while (3.3) needs a definition of the business cycle component. Burns and Mitchell (1946) is the seminal contribution to the measurement of business cycles. They proposed a decomposition that is no longer in common use. Instead, modern empirical macroeconomics employ a variety of detrending and smoothing techniques to carry out trend-cycle decompositions. Examples of these techniques are application of two-sided moving averages, first differencing, removal of linear or quadratic time trends and applications of the Hodrick and Prescott (1997) filter.

**3.1. The Hodrick-Prescott filter.** The Hodrick-Prescott (HP) filter is particularly widely used in real business cycle models to detrend macroeconomic time series and concentrate on the stylized facts of an economy along the business cycle. See, e.g., Harvey and Jaeger (1993), King and Rebelo (1993), Cogley and Nason (1995), Guay and St-Amant (1997), Canova (1998), Ehglen (1998), Baxter and King (1999), and Kaiser and Maravall (1999).

The basis of the filter is as follows: Starting from equation (3.2), they define the permanent component  $z_t^g$  of the series as the solution to the optimization problem

$$\min_{z_t^g} \sum_{t=1}^T \left[ (z_t - z_t^g)^2 + \lambda (\Delta^2 z_{t+1}^g)^2 \right]. \quad (3.4)$$

The first term of (3.4) might be regarded as a measure of the goodness of fit of the trend component to the observed series, while the second one imposes a penalty in order to obtain a smooth trend component. King and Rebelo (1993) show that the infinite-sample version of the HP filter defines the cyclic component of  $z_t$  as  $z_t^c = H(L)z_t$ , where

$$H(L) = \frac{\lambda(1-L)^2(1-L^{-1})^2}{1 + \lambda(1-L)^2(1-L^{-1})^2}, \quad (3.5)$$

that is an optimal linear filter in the sense of minimum mean squared error.

On the other hand, letting  $F(L) = 1 - H(L)$ , from (3.5) it follows that the growth HP filter has expression

$$F(L) = \left[1 + \lambda(1-L^{-1})^2(1-L^2)\right]^{-1} \times \left[\lambda L^2 - 4\lambda L + (1+6\lambda) - 4\lambda L^{-1} + \lambda L^{-2}\right]^{-1}, \quad (3.6)$$

which turns out to be a symmetric infinite order low-pass filter that must be approximated for practical purposes. In this respect, one possibility would be to truncate its weights at some fixed lag  $n$ . However, in actual practice, an alternative procedure is as follows. First, stack the data into a column vector  $X$ . Second, define a matrix  $\Gamma$  that links the corresponding vector of trend components,  $X^g$ , to the data:  $X = \Gamma X^g$ . The matrix  $\Gamma$  is implied by equation (3.6), i.e.,

$$x_t = \lambda x_{t+2}^g - 4\lambda x_{t+1}^g + (1+6\lambda)x_t^g - 4\lambda x_{t-1}^g + \lambda x_{t-2}^g, \quad (3.7)$$

with some modifications near the endpoints:

$$x_1 = (1+\lambda)x_1^g - 2\lambda x_2^g + (1+\lambda)x_3^g,$$

and

$$x_2 = -2\lambda x_1^g + (1+5\lambda)x_2^g - 4\lambda x_3^g + \lambda x_4^g.$$

Comparable modifications must be made near the end of the sample. Finally, the growth HP filter is given by  $X^g = \Gamma^{-1}X$ . This alternative procedure has the attractive property that there is no loss of data from filtering.

The values of the smoothing parameter  $\lambda$  suggested by Kydland and Prescott (1990) are  $\lambda = 1600$  for quarterly data and  $\lambda = 400$  for annual data, since these are the values for the ratios of the volatility of the cycle component relative to the volatility of the growth component. However, for reasons that will become clear later on, we also analyze other values of  $\lambda$ .

**3.2. The Baxter and King filter.** Application of the HP filter is frequently ad hoc in the sense that the researcher only looks for a stationary business cycle component without explicitly specify the statistical characteristics of business cycles. By contrast, Baxter and King (1999) develop methods for measuring business cycles that require the researcher begin by specifying such as characteristics. Technically, they develop approximated *band-pass filters*, i.e., filters passing only frequencies between  $\underline{\omega}$  and  $\bar{\omega}$  of the corresponding spectrum. See, e.g., Christiano and Fitzgerald (1999). These band-pass filters turn out to be moving averages of infinite order. In fact, most of the filters used in macroeconomic time series are two-sided moving averages, say  $h(L) = \sum_{j=-\infty}^{\infty} h_j L^j$ , that, for practical purposes, have to be approximated by a finite two-sided moving average of order  $p$ ,  $h_p(L) = \sum_{j=-n}^n h_j L^j$ . We will further specialize the analysis to symmetric moving averages where  $h_j = h_{-j}$  for all  $j$ .

The implications of those two-sided filters are clearly seen in the frequency domain by looking at the corresponding *frequency response functions*. The frequency domain function of the two-sided  $MA(\infty)$  equation is defined as

$$\beta(\omega) = \sum_{j=-\infty}^{\infty} b_j e^{-i\omega j}, \quad (3.8)$$

while for the finite two-sided  $MA(n)$ , the frequency domain function is

$$\alpha(\omega) = \sum_{j=-n}^n a_j e^{-i\omega j}. \quad (3.9)$$

King and Rebelo (1993) show that the optimal (in the sense of minimizing the mean squared error of the discrepancy  $\delta(\omega) = \beta(\omega) - \alpha(\omega)$ ) approximating filter for given maximum lag length  $n$ , is constructed by simply setting  $a_j = b_j$  for  $j = 0, 1, \dots, n$ , and  $a_j = 0$  for  $j \geq n + 1$ . Moreover, they also prove that symmetric moving average with weights summing up to zero, i.e.,  $\sum_{j=-n}^n a_j = 0$ , has trend elimination properties. In fact, these moving averages make stationary series containing quadratic deterministic trends or even I(1) or I(2) processes. Note that  $\sum_{j=-n}^n a_j = 0$  if and only if  $\alpha(0) = 0$ .

These trend reducing filters are called *high-pass filters* because they pass components of the data with frequency larger than a predetermined value  $\bar{\omega}$  close to zero, i.e.,  $\beta(\omega) = 0$  for  $|\omega| < \bar{\omega}$  and  $\beta(\omega) = 1$  for  $|\omega| \geq \bar{\omega}$ . By contrast, the so-called *low-pass filters* retain only slow-moving components of the data. An ideal symmetric low-pass filter passes only frequencies  $-\underline{\omega} \leq \omega \leq \underline{\omega}$ , having frequency-response function given by  $\beta(\omega) = 1$  for  $|\omega| \leq \underline{\omega}$  and  $\beta(\omega) = 0$  for  $|\omega| > \underline{\omega}$ . Therefore, low frequencies (long term movements) remain unchanged while others are canceled

out. In terms of the finite symmetric  $MA(n)$  filter, this means that low-pass filters must satisfy  $\sum_{j=-n}^n a_j = 1$ .

Letting  $b(L) = \sum_{j=-\infty}^{\infty} b_j L^j$  denote the time-domain representation of the ideal infinite-order low-pass filter, King and Rebelo (1993) show that the filter weights  $b_j$  can be found by the inverse Fourier transform of the frequency response function, i.e.,

$$b_j = \frac{1}{2\pi} \int_{-\pi}^{\pi} \beta(\omega) e^{i\omega j} d\omega,$$

yielding  $b_0 = \underline{\omega}/\pi$  and  $b_j = \sin(j\underline{\omega})/j\pi$ ,  $j = 1, 2, \dots$ . The complementary high-pass filter has coefficients  $(1 - b_0)$  at  $j = 0$  and  $-b_j$  for  $j = 1, 2, \dots$ . While the weights tend to zero as  $j$  becomes large, notice that an infinite-order moving average is necessary to construct the ideal filter. This leads to consider approximation of the ideal filter with a finite moving average  $a(L) = \sum_{j=-n}^n a_j L^j$ .

Usually, the definition of business cycle is associated with the NBER business cycle duration as defined by Burns and Mitchell (1946) where  $\underline{\omega}$  corresponds to 32 quarters (eight years) and  $\bar{\omega}$  to six quarters (eighteen months). So, the trend component is obtained with a low-pass filter with cycles of duration of eight years or less,  $\underline{\omega} = \pi/4$ . This low-pass filter is what we call BK filter in the Monte Carlo simulations.

**3.3. Nonlinear filters.** The HP and BK filters are examples of linear filters. For completeness, herein we will also consider a class of nonlinear filters, called the *median filters* (Wen and Zeng, 1999), that has been proven very useful in recent years in signal processing in the field of electrical engineering. Median filters have two interesting properties: edge (sharp change) preservation and efficient noise attenuation with robustness against impulsive-type noise. Neither can be achieved by traditional linear filtering techniques. To compute the output of a median filter, an odd number of sample values are sorted, and the middle or median value is used as the filter output. If the filter length is  $2n + 1$ , the filtering procedure is denoted as

$$\text{med}\{x_{t-n}, x_{t-n+1}, \dots, x_t, \dots, x_{t+n}\}. \quad (3.10)$$

To be able to filter also the outmost input samples, where parts of the filter window fall outside the input signal, the time series is appended to the required size.

Frequency analysis and impulse response have no meaning in median filtering since the impulse response of a median filter is zero. Nonetheless, one very important property of the median filter is the so-called *root-convergence* property, namely, any finite sample time series contains a root signal set that is invariant to the median filtering. From an economic point of view, this invariant property

is of interest because it makes possible that possible structural shifts of economic fundamentals be not disturbed by the filtering operation. See Wen and Zeng (1999) for further details.

#### 4. FILTERING UNIT ROOT PROCESSES

From Section 2 we learn that testing for a unit root in the presence of systematic AO's is similar to testing for a unit root in the presence of MA errors. This might suggest the use of more general tests like the ADF and PP tests or the use of unit root statistics robust to MA errors, such as the modifications to the PP statistics proposed by Perron and Ng (1996). Indeed, Vogelsang (1999) reports some experimental evidence showing the good size and power properties of these modified PP statistics when there are outliers. In this sense, his paper and the present article can be viewed as complements rather than substitutes.

Herein we study two different possibilities to test for a unit root in the presence of AO's. First, we are interested in trying to approximate the temporary AO's by adding lags of the contaminated series  $x_t$  in equation (2.2), and therefore estimate the model

$$\Delta x_t = c + \rho x_{t-1} + \sum_{i=1}^p \phi_i \Delta x_{t-i} + \eta_t, \quad (4.1)$$

where the number of lags,  $p$ , chosen for instance by means of an order selection criteria, is such that  $\eta_t$  is a white noise process. Of course, using the  $t$  statistic of  $\rho$  in equation (4.1) to test for the null hypothesis  $\rho = 0$  is nothing else than the customary ADF test.

Second, we want to analyze the impact of applying unit root tests to the trend component,  $x_t^g$ , of the observed series  $x_t$ . The basic goes as follows. Let  $x_t$  be split into the unobserved components  $x_t^g$  and  $x_t^c$  as in equation (3.1). By substituting in (2.6) we have

$$\Delta x_t^g = \rho x_{t-1}^g + \xi_t, \quad (4.2)$$

where  $\xi_t = u_t - \Delta x_t^c = \varepsilon_t - \Delta(x_t^c - \theta \delta_t)$  under the null  $\rho = 0$ . Now, since the AO's generated by  $\delta_t$  are transitory, they should be incorporated, to a large extent, into the cyclical component and not into the trend. Consequently,  $(x_t^c - \theta \delta_t)$  would be an I(0) series free of AO's that can be well approximated by adding autoregressive terms of  $\Delta x_t^g$  in equation (4.2).

In order to obtain  $x_t^g$ , one can use (approximate) low-pass linear filters, i.e.,

$$x_t^g = a(L) x_t = \sum_{j=-n}^n a_j x_{t-j}, \quad (4.3)$$

with  $\sum_{j=-n}^n a_j = 1$ . There is no "best" choice of  $n$ . Increasing  $n$  leads to a better approximation to the ideal infinite-dimensional filter, but results in more lost observations at the beginning and end of the sample. Thus, the choice of  $n$  in a particular instance will depend on the length of the sample and the importance attached to obtaining an accurate approximation to the ideal filter. Nowadays, after some experimentation, Baxter and King (1999) suggest to use moving averages based on three years of past data and three years of future data, as well as the current observation, when working with both quarterly and annual time series. Moreover, following Baxter and King's suggestions, we require that the low-pass filter be *symmetric* ( $a_j = a_{-j}$ ,  $j = 1, 2, \dots, n$ ) and *time invariant*, with coefficients not depending on the point in the sample. These requirements prevent from filters introducing *phase shift* (i.e., altering the timing relationships between series at some frequency) and dependencies on the length of the sample period.

Now, denote by  $\widehat{\rho}_{AO}^g$  and  $t_{\widehat{\rho}_{AO}^g}$  the Dickey-Fuller statistics when applied to equation (4.2), i.e.,

$$\widehat{\rho}_{AO}^g = \left( \sum_{t=1}^T x_{t-1}^g \Delta x_t^g \right) / \left( \sum_{t=1}^T (x_{t-1}^g)^2 \right), \quad (4.4)$$

and

$$t_{\widehat{\rho}_{AO}^g} = \widehat{\rho}_{AO}^g / \widehat{\sigma}_x^g \left( \sum_{t=1}^T (x_{t-1}^g)^2 \right)^{-1/2}, \quad (4.5)$$

with  $\widehat{\sigma}_x^g = \left( T^{-1} \sum_{t=1}^T (\Delta x_t^g - \widehat{\rho}_{AO}^g x_{t-1}^g)^2 \right)^{1/2}$ . Further, assume, without loss of generality, the initial condition  $x_0^g = 0$ . The limiting behavior of  $\widehat{\rho}_{AO}^g$  and its  $t$  ratio can now be stated as follows.

**Theorem 1.** *Let  $T > 2n + 1$  for fixed  $n$ . Then, as the sample size grows large, we have that*

$$T \widehat{\rho}_{AO}^g \Rightarrow \left( \int_0^1 W(r) dW(r) + \Phi \right) \left( \int_0^1 W^2(r) dr \right)^{-1} \quad (4.6)$$

$$t_{\widehat{\rho}_{AO}^g} \Rightarrow \Psi \left( \int_0^1 W(r) dW(r) + \Phi \right) \left( \int_0^1 W^2(r) dr \right)^{-1/2} \quad (4.7)$$

where

$$\begin{aligned} \Phi &= \frac{1}{2} \sum_{j=-n}^n a_j (1 - a_j) - (\theta/\sigma_\varepsilon)^2 \pi \sum_{j=-n}^n a_j (a_j - a_{j-1}) \\ \Psi &= \left[ \sum_{j=-n}^n a_j^2 + 2(\theta/\sigma_\varepsilon)^2 \pi \sum_{j=-n}^n a_j (a_j - a_{j-1}) \right]^{-1/2}. \end{aligned}$$

Therefore, as in the unfiltered case,  $\rho$  is estimated (super-) consistently with the limiting distributions having nuisance parameters depending now on  $\theta, \pi, \sigma_\varepsilon^2, n$  and the weights  $\{a_j\}_{j=-n}^n$ . When

$n = 0, a_0 = 1$ , we recover expressions (2.9) and (2.10). Note that, if we choose a sequence of weights such that  $\sum_{j=-n}^n a_j^2 \approx \sum_{j=-n}^n a_j a_{j-1} \approx 1$ , then  $\Phi \approx 0$  and  $\Psi \approx 1$ , independently of the AO's and for all  $n$ . In the particular case where  $a_j = 1/(2n+1)$  for  $j = -n, \dots, n$ ,  $\Phi$  and  $\Psi$  become

$$\Phi = \frac{n}{2n+1}, \quad (4.8)$$

$$\Psi = \left[ \frac{1}{2n+1} \right]^{-1/2}. \quad (4.9)$$

Actually, this *uniform* or *moving average* low-pass filter,

$$x_t^g = \frac{1}{2n+1} \sum_{j=-n}^n x_{t-j}, \quad (4.10)$$

where the growth or trend component is defined as a two-sided or centered moving average, is a widely used method of detrending economic time series.

In Figure 1 we displayed the empirical density functions for the Dickey-Fuller (no constant, no lags)  $t$  test using equation (2.5) and equation (4.5) with the HP ( $\lambda = 10$ ), the BK and the median filters, for a sample size of  $T = 1000$  and for  $\pi = 0.1, \theta = 16$ , i.e, in the presence of large and frequent AO's. For comparison purposes, we have also included the customary Dickey-Fuller distribution without AO's. It is clear the huge shift to the left of the Dickey-Fuller distribution in the presence of AO's, as well as the apparent gains from using the different filtered versions of the Dickey-Fuller distribution.

[Figure 1 about here.]

## 5. EXPERIMENTAL EVIDENCE

Herein we provide some Monte Carlo evidence on the numerical implications of our analytical findings. The data is generated according to the following data generating process (DGP),

$$\Delta y_t = \rho y_{t-1} + \varepsilon_t, \quad \varepsilon_t \sim N(0, 1),$$

$$x_t = y_t + \theta \delta_t,$$

with  $\pi = 0, 0.01, 0.05, 0.10$ ,  $\theta = 1, 6, 16$  and  $T = 100, 200, 500, 1000$ . We considered that at most 10% of the series  $y_t$  is contaminated, which is standard in this kind of studies, see, e.g., Franses and Haldrup (1994). However, they consider breaks of sizes 3, 4 and 5, while we consider more abrupt ones. The full factorial design means that we have 48 cases for the Monte Carlo experiment. In order to obtain the critical values, we simulate the DGP under  $H_0 : \rho = 0$ , and consider the lower 5% tail of the ordered Dickey-Fuller  $t$ -statistics  $t_{\hat{\rho}_{AO}}$  and  $t_{\hat{\rho}_{AO}^g}$  as the critical values of interest. The

power of the tests has been obtained by simulating the DGP under  $H_1 : \rho = -0.2$ , and computing the percentage of rejections using the critical values previously obtained. For all experiments, 10,000 replications of the DGP were used.

In our experiments, HP stands for the HP filter, BK stands for the low-pass Baxter and King filter, U stands for the uniform or moving average filter, and MD stands for the median filter. With respect to the HP filter, we choose different values of the smoothing parameter  $\lambda$ , namely,  $\lambda = 10, 100, 400$  and  $1600$ . The window parameter of the BK, U and MD filters were set at  $n = 3$ , implying a window size of  $2n + 1 = 7$ . The number of lags ( $p$ ) of the ADF test were chosen by means of the SIC criterion. The results are reported in Tables 1 to 5.

[Table 1 about here.]

[Table 2 about here.]

Consider first the effects of AO's on the standard Dickey-Fuller tests. The estimated regressions are given by

$$\Delta x_t = c + \rho x_{t-1} + \eta_t, \quad (5.1)$$

and

$$\Delta x_t = c + \rho x_{t-1} + \sum_{i=1}^p \phi_i \Delta x_{t-i} + \eta_t. \quad (5.2)$$

From Table 1 we learn that the critical values of  $t_{\hat{\rho}_{AO}}$  are very unstable in the case of model (5.1), ranging from -2.85 ( $\pi = 0$ ) to -17.319 ( $\pi = 0.1$ ) for  $T = 1000$  and  $\theta = 16$ . With respect to model (5.2), we can see in Table 1 that in the case of no AO's ( $\pi = 0$ ), critical values are virtually the same as in the case of no lags, which indicates that the lag order selection criterion works well. Nonetheless, the critical values are still very unstable, ranging from -2.9 to -11, for  $T < 500$ , but more stable for  $T > 500$ , ranging from -2.85 to -6. In turn, the size adjusted power of  $t_{\hat{\rho}_{AO}}$  against  $H_1 : \rho = -0.2$  is good for  $T > 100$  in both cases as we can see from Table 2.

Consider now the behavior of  $t_{\hat{\rho}_{AO}^g}$ . The estimated model is

$$\Delta x_t^g = c + \rho x_{t-1}^g + \sum_{i=1}^p \phi_i \Delta x_{t-i}^g + \xi_t. \quad (5.3)$$

[Table 3 about here.]

[Table 4 about here.]

As we can see in Table 3, the critical values are very stable for sample sizes as small as 100 in the case of the HP filter and 200 when using the BK filter. For instance, the critical values range from -2.8 to -3.22 in this latter case. As regards the HP filter, the critical values obtained from

the different values of  $\lambda$  are not very different, specially for medium to large sample sizes. Critical values are also fairly stable with respect to  $\pi, \theta$  and  $T$  when using the U and MD filters. Overall, from our simulations it shows up that the most stable critical values are obtained when using the MD filter. It is interesting to note that when there are no AO's, the detrending procedure or the value of  $\lambda$  does not affect, to a large extent, the critical value. In fact, in that case the critical values obtained with the trend component are similar to those obtained with the observed series. On the other hand, (size adjusted) power is high in all cases for medium to large sample sizes. See Table 4. It is not as high as the unfiltered case for small sample sizes, which is an expected result (cf. Ghysels and Perron, 1993).

Finally, it is also of interest to analyze the robustness of the critical values obtained so far in Tables 1 and 3. In particular, in Table 5 we present some results concerning the empirical sizes obtained from the different testing procedures when using the critical values for the  $\pi = 0$  case. It is particularly noticeable the size distortions of the ADF test in model (5.2) specially for  $\theta = 16$ , and the good performance of the MD filter for any value of  $\pi, \theta$  and  $T$  included in the Monte Carlo design.

[Table 5 about here.]

Figures 2 and 3 provide the graphical counterpart to the previous comments on the stability of the critical values. Note in particular that the distribution of the MD filtered version of the ADF test is virtually the same with and without AO's (Figures 2.e and 3.e), in contrast with the unfiltered version of the ADF test (Figures 2.a and 3.a). On the other hand, the size problems of the BK filtered version of the ADF test come up after looking at the different left tails for  $T = 100$  (Figure 2.d) and  $T = 200$  (Figure 3.d). All these findings are in full agreement with the results obtained in Table 5.

[Figure 2 about here.]

[Figure 3 about here.]

## 6. EMPIRICAL APPLICATION

The above procedures were applied to the US/Finland exchange rate series (in logarithms) based on the consumer price index (CPI). See Figure 4. The data is annual and spans the years 1900-1988. This series was analyzed by Perron and Vogelsang (1992) in the context of testing for a unit root in the presence of a changing mean at an unknown date. They did not consider the possibility of AO's in the data. By conducting an ADF test as in model (5.2) with  $p = 1$ , they found a  $t$  ratio of -5.74 (5% critical value = -2.89). Thus, the unit root hypothesis was rejected for this series.

[Figure 4 about here.]

Franses and Haldrup (1994) (FH94, henceforth) pointed out that the series may contain additive outlying observations so that the results by Perron and Vogelsang (1992) may be biased towards false rejection of the unit root hypothesis. Using the methods to detect outliers of Chen and Liu (1993) as implemented in the TRAMO Program (Gómez and Maravall, 1996), FH94 found evidence of AO's in the series.

To remove the influence of outliers, FH94 suggested to conduct the model

$$\Delta x_t = c + \rho x_{t-1} + \sum_{i=1}^p \phi_i \Delta x_{t-i} + \sum_{i=0}^{p+1} \omega_i D_{t-i}^i + \eta_t, \quad (6.1)$$

where we test whether  $\rho = 0$  by using the ADF  $t$  ratio.  $D^i$  indicates impulse dummy variable taking the value 1 at the time the outlier occurrence takes place and 0 otherwise.

FH94 reported the following (most significant) AO's: 1917-1919, 1932, 1933, 1945, 1949 and 1950. This means an empirical percentage of AO's of about  $\hat{\pi} = 0.09$ . The ADF  $t$  ratio in model (6.1) with  $p = 2$  was -2.65 which fails to reject the unit root hypothesis at the 5% level.

On the other hand, Vogelsang (1999) (V99, henceforth) proposes a second procedure for detecting AO's which is related to the approach suggested by FH94. The procedure is based on the following regression estimated by OLS:

$$x_t = c + \alpha D_t^i + \eta_t. \quad (6.2)$$

Let  $t_\alpha^i$  denote the  $t$  statistic for testing  $\alpha = 0$  in (6.2). Then, V99 suggests to test for the presence of AO's using  $\tau = \sup_{i=1,2,\dots,T} |t_\alpha^i|$ . The asymptotic distribution of  $\tau$  is nonstandard but asymptotic critical values has been tabulated by V99.

V99 applied the  $\tau$  statistic to the CPI-based data in an iterative manner detecting the following AO's: 1917, 1918, 1919, 1921 and 1932. To remove the influence of the outliers on the unit root test, regression (6.1) was used with  $p = 0$ . The ADF  $t$  ratio was -3.51, rejecting the unit root hypothesis at the 5% level in contrast with FH94's results.

These differences clearly illustrate the sensitivity of unit root tests to the choice of dummy variables and choices of lag length and led V99 to suggest the use of the modifications to the Phillips-Perron statistics proposed by Perron and Ng (1996) to the data without searching for or removing outliers. For the CPI-based series the modified PP statistics,  $MZ_\alpha$  and  $MZ_t$ , defined in (6.3)–(6.5), reject the unit root hypothesis at any reasonable significance level.

Consider now the application of  $t_{\hat{\rho}_{AO}^g}$  in model (5.3) to the CPI-based series. In view of the simulations in Section 5, we only report the results obtained with the BK, the HP10 and the MD filters.

[Table 6 about here.]

In Table 6, the column  $CV_f$  stands for the 5% critical values of  $t_{\hat{\rho}_{AO}^g}$  in model (5.3) assuming  $\pi = 0$  and a sample size  $T = 89$ , the number of observations of the CPI-based real exchange rate. Under this assumption, only the BK filter suffers from size distortions, see Table 5.  $CV_f^*$  is the critical value of the tests assuming that the series includes outliers at the same positions and with the sizes reported by V99. From Table 6, it turns out that we fail to reject the unit root hypothesis at the 5% significance level with any of the filter procedures, in contrast with V99's findings and in accordance with FH94's claims. However, with the BK and MD filters, the  $p$ -values are around 0.07 and 0.08 when using the corresponding  $CV_f$ , and 0.07 and 0.09 when using  $CV_f^*$ , respectively.

In light of Table 4, a possible explanation for such discrepancies could be the small power of the filtered unit root tests in small samples. Accordingly, Figures 5 and 6 plot the (size adjusted) power of the ADF tests for the original and the filtered data with ( $\pi = 0.1, \theta = 16$ ) and without AO's, and for  $T = 100$  (Figure 5) and  $T = 200$  (Figure 6). For completeness, we have also included the  $MZ_t$  statistic proposed by Perron and Ng (1996), defined as

$$MZ_\alpha = \frac{T^{-1}\tilde{x}_T^2 - s^2}{2T^{-2}\sum_{t=1}^T\tilde{x}_t^2} \quad (6.3)$$

$$MSB = \sqrt{T^{-2}\frac{\sum_{t=1}^T\tilde{x}_{t-1}^2}{s^2}} \quad (6.4)$$

$$MZ_t = MSB \times MZ_\alpha \quad (6.5)$$

where  $\tilde{x}_t$  is the GLS-demeaned series, and we take  $s_{AR}^2$  as the estimator of  $s^2$  (see Ng and Perron, 1998, Vogelsang, 1999).

$$s_{AR}^2 = \frac{s_{ek}^2}{(1 - \hat{\phi}(1))^2}, \quad (6.6)$$

and  $s_{ek}^2 = T^{-1}\sum_{t=k+1}^T\hat{e}_{tk}^2$ ,  $\hat{\phi}(1) = \sum_{j=1}^k\hat{\phi}_j$ , where  $\hat{\phi}_j$  are  $\{\hat{e}_{jk}\}$  obtained from the autoregression

$$\Delta\tilde{x}_t = b\tilde{x}_{t-1} + \sum_{j=1}^k\phi_j\Delta\tilde{x}_{t-j} + e_{jk}.$$

The order of this autoregression,  $k$ , is chose by the MIC criterion as proposed by Ng and Perron (1998).

[Figure 5 about here.]

[Figure 6 about here.]

A first remarkable conclusion of Figures 5 and 6 is the small power of the  $MZ_t$  statistic for non-local alternatives when no outliers are present in the data, in contrast with the filtered unit root tests (Figures 5.a and 6.a). In the presence of AO's and for  $T = 100$  (Figure 5.b) the power of the MD and HP10 filtered unit root tests are uniformly smaller than the power of the rest of the ADF tests. The highest power corresponds to the  $MZ_t$  statistic for local alternatives and to the ADF and BK filtered tests for non-local alternatives. For  $T = 200$  (Figure 6.b) the power of the  $MZ_t$  statistic is not the highest one even for local alternatives. In fact, it has the smallest power for non-local alternatives.

From all the preceding analysis, thus, it turns out that in order to test for a unit root in the presence of AO's one can propose to use the  $MZ_t$  statistic along with size adjusted versions of the original ADF and BK filtered ADF tests. However, we know that the latter tests have size problems in small to medium sample sizes.

To correct these size problems, Arranz (2001) has recently considered the use of bootstrap resampling techniques. In particular, he shows how the small sample size distortions of the BK filtered ADF test can be corrected to a large extent by means of the following bootstrap procedure:

(1) Estimate the *restricted* model

$$\Delta x_t^g = c + \sum_{i=1}^p \phi_i \Delta x_{t-i}^g + \nu_t.$$

(2) Resample residuals  $\nu_t^*$  and build  $x_t^{g*}$  using the model

$$\Delta x_t^{g*} = c + \sum_{i=1}^p \phi_i \Delta x_{t-i}^{g*} + \nu_t^*.$$

The size of the reconstructed series is  $m = T^{3/4}$  in order to solve the problem of the distribution discontinuity (see Datta, 1996).

(3) Estimate the model

$$\Delta x_t^{g*} = c + \rho x_{t-1}^{g*} + \sum_{i=1}^p \phi_i \Delta x_{t-i}^{g*} + \xi_t,$$

obtaining  $\hat{\rho}^*$  and the corresponding customary  $t$ -statistic,  $t^*$ . Repeat steps (2) – (3)  $NB$  times, where  $NB$  indicates the number of bootstrap resamples. The bootstrap critical value is obtained by looking at the 5% lower tail of the empirical distribution of  $t^*$ .

The bootstrap critical values ( $NB = 10,000$ ) for the CPI-based US/Finland exchange rate series and for the different filtering procedures are collected in Table 6, column  $CV_b$ . Note, as expected,

the similarity of the Monte Carlo and the bootstrap critical values for the MD filtered unit root tests. More interestingly, note that now the BK filtered ADF test rejects the unit root null hypothesis according with the bootstrap 5% critical value (the  $p$ -value is 0.045), in agreement with V99. In the case of the MD filtered case, the  $p$ -value of the bootstrap test is 0.0762.

Finally, the trend component of the CPI-based US/Finland exchange rate series with respect to the HP10, the BK and the median filters are graphed in Figure 7. Note that the linear filters are not so efficient as the median filter in retaining the signal component of the CPI-based series in terms of effectively capturing sharp changes in the trend component.

[Figure 7 about here.]

## 7. CONCLUSIONS

Time series observations are often influenced by interruptive events such as strikes, outbreaks of wars, sudden political or economic crises, or even unnoticed errors of typing and recording. The consequences of these interruptive events create spurious observations, which are inconsistent with the rest of the series. Such observations are usually referred to as outliers.

In this paper we propose two different ways of addressing the question of testing for unit roots in the presence of additive outliers. The first approach considers the possibility of adding extra dynamic terms to the Dickey-Fuller equation. By means of Monte Carlo simulations we show that the critical values are more stable than the ones obtained without any dynamic term as suggested by the data generating process. Nonetheless, the stability (robustness) of the critical values is further increased by our second approach which suggest to run the Dickey-Fuller tests on the trend or permanent component of the series, obtained by either linear or nonlinear filtering techniques. Simulations show that this procedure is robust to additive outliers in terms of size and power. Specially remarkable is the robustness of the nonlinear median filter.

In order to test for a unit root in the presence of additive outliers, our analysis suggests the use of the  $MZ_t$  statistic for local alternatives, the bootstrap version of the BK filtered ADF test in small samples and for global alternatives, and the normal (or bootstrap) version of the BK filtered ADF test in medium to large samples and global alternatives.

On the other hand, it appears that the median filter can be more useful than the linear filters in obtaining the trend-cycle decompositions of the underlying series because of its greater capability of tracing sharp changes in removing the stochastic trend component of a time series.

## APPENDIX A. PROOF OF THEOREM 1

Denote by  $a(L)$  a general symmetric low-pass filter of order  $n$ , i.e., a linear filter  $a(L) = \sum_{j=-n}^n a_j L^j$  for which  $a(L) = a(L^{-1})$  and  $a(1) = 1$ . Let  $x_t^g = a(L)x_t$  denote the filtered version of  $x_t$  in equation (2.2), so that  $x_t^g = x_{t-1}^g + \xi_t$ ,  $\xi_t = a(L)u_t$  under the unit root hypothesis, with  $u_t = \varepsilon_t + \theta\Delta\delta_t$ . Let  $\sigma_u^2 = \lim_{T \rightarrow \infty} T^{-1}E\left(S_{T,u}^2\right)$  and  $\sigma_\xi^2 = \lim_{T \rightarrow \infty} T^{-1}E\left(S_{T,\xi}^2\right)$ , where  $S_{t,u} = \sum_{j=1}^t u_j$  and  $S_{t,\xi} = \sum_{j=1}^t \xi_j$ ,  $t = 1, 2, \dots, T$ . Note that both  $u_t$  and  $\xi_t$  satisfy Phillips' (1987) mixing conditions for the application of a functional central limit theorem to their partial sums, yielding

$$T\widehat{\rho}_{AO}^g \Rightarrow \frac{\int_0^1 W(r) dW(r) + \lambda_\xi/\sigma_\xi^2}{\int_0^1 W^2(r) dr} \quad (\text{A.1})$$

and

$$t\widehat{\rho}_{AO}^g \Rightarrow \left(\frac{\sigma_\xi}{s_\xi}\right) \frac{\int_0^1 W(r) dW(r) + \lambda_\xi/\sigma_\xi^2}{\left(\int_0^1 W^2(r) dr\right)^{1/2}}, \quad (\text{A.2})$$

where  $\lambda_\xi = 1/2\left(\sigma_\xi^2 - s_\xi^2\right)$  and  $s_\xi^2 = \text{var}(\xi_t)$ . From Franses and Haldrup (1994) we have that  $\sigma_u^2 = \sigma_\varepsilon^2$ , which, in turn, implies that  $\sigma_\xi^2 = \sigma_u^2$  using the fact that  $a(1) = 1$ . The variances of the processes  $u_t$  and  $\xi_t$  are however, different. Franses and Haldrup prove that  $s_u^2 = \text{var}(u_t) = \sigma_\varepsilon^2\left(1 + 2(\theta/\sigma_\varepsilon)^2\pi\right)$ . By contrast,

$$s_\xi^2 = \text{var}(a(L)u_t) = \sum_{j=-n}^n \sum_{i=-n}^n a_j a_i \text{cov}_u(j-i). \quad (\text{A.3})$$

As noted in the main text,  $u_t$  is an  $MA(1)$  process with autocovariance function

$$\text{cov}_u(k) = \begin{cases} \sigma_\varepsilon^2(1 + 2(\theta/\sigma_\varepsilon)^2\pi) & k = 0 \\ -\theta^2\pi & k = 1 \\ 0 & k > 1 \end{cases} \quad (\text{A.4})$$

Therefore, using (A.4) and the properties of  $a(L)$ , it can be proved after some algebra that

$$s_\xi^2 = s_u^2 \sum_{j=-n}^n a_j^2 - 2\theta^2\pi \sum_{j=-n}^n a_j a_{j-1}, \quad (\text{A.5})$$

which, in turn, implies

$$\lambda_\xi/\sigma_\xi^2 = \frac{1}{2} \left[ 1 - \sum_{j=-n}^n a_j^2 - 2(\theta/\sigma_\varepsilon)^2 \pi \sum_{j=-n}^n a_j^2 + 2(\theta/\sigma_\varepsilon)^2 \pi \sum_{j=-n}^n a_j a_{j-1} \right] = \Phi, \quad (\text{A.6})$$

and

$$\left( \frac{\sigma_\xi}{s_\xi} \right)^2 = \left[ \sum_{j=-n}^n a_j^2 + 2(\theta/\sigma_\varepsilon)^2 \pi \sum_{j=-n}^n a_j (a_j - a_{j-1}) \right]^{-1} = \Psi^2. \quad (\text{A.7})$$

The theorem is finally proved by substituting (A.6) and (A.7) in expressions (A.1) and (A.2).

FIGURE 1. Density Estimation of the  $t$  DF test (no constant, no lags) under the unit root null hypothesis, based on 50000 replications.  $T = 1000$ .  $\pi = 0.1$  and  $\theta = 16$ . DF wo AO and DF refer to the distributions of the  $t$ -stat in expressions (2.5) and (2.8), respectively; HP10, BK and MD refer to the distribution of the  $t$ -stat in expression (4.5), using the Hodrick–Prescott (with  $\lambda = 10$ ), the Baxter–King and the median filters

TABLE 5. Size of the ADF and filtered unit root tests with AO's. Critical values obtained from Tables 1 and 3 with  $\pi = 0$

	$p$	$t_{\hat{\rho}_{AO}}^g$	$CV_f$	$CV_f^*$	$CV_b$
HP10	4	-1.4576	-3.2314	-3.1592	-2.8572
MD	1	-2.6381	-2.9376	-2.8983	-2.8924
BK	3	-2.8261	-3.0074	-3.0475	-2.7510

TABLE 6. Filtered ADF tests on CPI-based US/Finland real exchange rates.  $CV_f$  stands for the 5% critical values of  $t_{\hat{\rho}_{AO}}^g$  in model (5.3) assuming  $\pi = 0$  and a sample size  $T = 89$ .  $CV_f^*$  is the 5% critical value of the tests assuming that the series includes outliers at the same positions and with the sizes reported by V99.  $CV_b$  is the 5% critical value obtained by bootstrap.
